Abstract. In the analysis of elastic-scattering experimental data, optical-model parameters (usually, depths of real and imaginary potentials) are fitted and conclusions are drawn analyzing their variations at bombardment energies close to the Coulomb barrier (threshold anomaly). The judgement about the shape of this variation (related to the physical processes producing this anomaly) depends on these fitted values but the robustness of the conclusions strongly depends on the uncertainties with which these parameters are derived. We will show that previous published studies have not used a common criterium for the evaluation of the parameter uncertainties. In this work, a study of these uncertainties is presented, using conventional statistic tools as well as bootstrapping techniques. As case studies, these procedures are applied to re-analyze detailed elastic-scattering data for the $^{12}\text{C} + ^{208}\text{Pb}$ and the $^6\text{Li} + ^{80}\text{Se}$ systems.

1. Introduction

In the study of elastic scattering of atomic nuclei at low energies there has been a long-lasting interest in the so-called threshold anomaly (TA [1]). For the case of tightly bound nuclei, this phenomenon, related to the closure of reaction channels, consists in a decrease of the depth of imaginary part of the optical potential at bombarding energies below the Coulomb barrier V_B . Due to the causality-related dispersion relation (DR [1]) linking the real and imaginary parts of optical potentials, the depth of the real part also varies strongly, peaking around V_B (see Refs. [2, 3, 1]). In the case of weakly bound projectiles, the coupling to nonelastic channels (e.g. breakup) generates a repulsive polarization potential [4] that can produce either the absence of TA (*no TA* [5, 6, 7, 8]) or the so-called breakup threshold anomaly (BTA [7, 9, 8]), in which the imaginary potential increases while approaching V_B and, conversely, there is a reduction on the real part of the potential [9, 10].

For an unambiguous determination of the kind of anomaly, the variation of the optical-model parameter values as a function of the energy must be evaluated taking into account their uncertainties (hereafter called *parameter uncertainties*), which must be derived from the experimental angular distribution data and their own uncertainties (hereafter called *experimental uncertainties*). However, publications on the subject apply different, sometimes non-rigorous criteria for the estimation of the parameter uncertainties or do not consider uncertainties at all. Here, a study of the parameter uncertainties is presented, using conventional statistic tools as well as the bootstrap technique [11]. It is hoped that these methods will help to achieve a better

determination of the parameters of interest in the characterization of the TA. In section 2 we discuss mathematical and physical issues that influence the determination of uncertainties when adjusting optical-model parameters using experimental angular distributions, in section 3 the $^{12}\text{C} + ^{208}\text{Pb}$ and the $^6\text{Li} + ^{80}\text{Se}$ systems will be reanalyzed and their uncertainties evaluated with different techniques. Finally, in section 4 we make our final remarks.

2. The determination of optical-model parameter uncertainties

In this section we will firstly consider the χ^2 test (2.1) since it is the most popular method to evaluate the optical-model parameter uncertainties, we will review the different χ^2 criteria found in the literature (2.2) and finally we will consider the two techniques that we will apply to the case studies in the next section, namely: *covariance ellipses* (2.3) and *bootstrap method* (2.4).

2.1. The χ^2 test

Let us consider a series of experimental pairs $x_i, y_i(x_i)$, where the y_i values have an uncertainty Δy_i (statistical, background subtraction, etc.) which is assumed to be normally distributed. To compare these experimental data with a theoretical model that adjust the data with a function $y = f(x)$ taking into account the experimental uncertainties, we could use an adjusting program that minimizes the value of χ^2 defined as

$$\chi^2 = \sum_i^N R_i^2 = \sum_i^N \left[\frac{y_i - f(x_i)}{\Delta y_i} \right]^2, \quad (1)$$

where N is the number of experimental points and R_i are the so-called *residuals*. The adjusting program should minimize the effective distance between the experimental results y_i and their theoretical estimation $f(x_i)$. The simplest case to study is the repetition of a measurement of a physical quantity (say a life-time or the speed of light) by several laboratory groups. The theoretical model $f(x_i)$ could be as simple as the construction of the best evaluated value of that physical quantity, e.g. the arithmetic or weighted average. In this simple case the expected χ^2 should be close to $N - 1$, where N is the number of measurements. If not, procedures such as the proposed by Birge [12, 13, 14] should be applied. In its original form, it applies for interlaboratory evaluations (external uncertainty) when $\chi^2/(N - 1) > 1$ and consists in multiplying the experimental (internal) uncertainties by $\sqrt{\chi^2/(N - 1)}$. With the increased uncertainties a new, normalized value $\chi^{2'}$ is obtained, here using N instead of $N - 1$ for large number of points:

$$\chi^{2'} = \sum_{i=1}^N \frac{[y_i - f(x_i)]^2}{\Delta Y_i^2} = \sum_{i=1}^N \frac{[y_i - f(x_i)]^2}{(\sqrt{\chi^2/N} \Delta y_i)^2} = \sum_{i=1}^N \frac{[y_i - f(x_i)]^2}{\Delta y_i^2} \left(\frac{N}{\chi^2} \right) = \chi^2 \left(\frac{N}{\chi^2} \right) = N \quad (2)$$

We consider now cases in which the theoretical function f has k parameters $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_k)$, denoted from now on as $f(x_i|\boldsymbol{\alpha})$, that should be adjusted to achieve the best fit of f to experimental data. It is a well-known rule [15, 11] that the uncertainty with which a single, uncorrelated parameter α_j is adjusted, can be obtained varying this parameter around its optimum value α_{j0} (while all others parameters are optimized) until the value of χ^2 increments in one unit, i.e.:

$$\chi^2 = \chi_0^2 + 1. \quad (3)$$

Here χ_0^2 denotes the minimum value of χ^2 . For this rule to be valid the following conditions must apply:

- The uncertainties of raw experimental data Δy_i are properly determined.

- There are no significant systematic errors.
- The theoretical model is a true description of the data being studied.

As consequence of the previous conditions the residuals R_i will follow a normal distribution with mean value $\langle R_i \rangle = 0$ and variance $\sigma_R^2 = 1$ (we will denote this $R_i \sim \mathcal{N}(0, 1)$) which implies $\chi_0^2 \sim \nu$ (although the reciprocal is not necessarily true). Here ν is the number of degrees of freedom $\nu = N - n_f$ being n_f the number of free parameters. In most of the cases $n_f = 2$ and $N \geq 20$, thus $\nu \approx N$ and no significant difference arises from the use of N instead of ν .

As we will see in section 2.2 many data sets analyzed in the area of low-energy elastic scattering do not fulfil all the conditions previously mentioned, but the rule of eq. 3 is nevertheless applied. Hence the uncertainty of the obtained parameters is underestimated. For these cases, we will extend the procedure of Birge (eq. 2) for the experimental adjustment of one or several parameters α of a theoretical function $f(x_i|\alpha)$ in the following way:

$$\chi^{2'} = \sum_{i=1}^N \frac{[y_i - f(x_i|\alpha)]^2}{(\sqrt{\chi_0^2/\nu} \Delta y_i)^2} = \frac{\chi^2}{(\chi_0^2/\nu)} \quad (4)$$

For the optimum set of parameters α_0 we obtain

$$\chi_0^{2'} = \frac{\chi_0^2}{(\chi_0^2/\nu)}. \quad (5)$$

Now, with the experimental uncertainties Δy_i scaled by the Birge factor $\sqrt{\chi_0^2/\nu}$ the rule of eq. 3 can be applied:

$$\chi^{2'} = \chi_0^{2'} + 1. \quad (6)$$

This does not imply that the experimental uncertainties Δy_i are effectively changed in fact the original ones should be reported. To avoid confusions we prefer to replace in eq. 6 with eq. 4 and 5 to obtain the equivalent rule

$$\chi^2 = \chi_0^2 + \chi_0^2/\nu. \quad (7)$$

In the case of adjusting several (even correlated) parameters the rule of eq. 1 should be extended as $\chi^2 = \chi_0^2 + \Delta\chi^2$, where for two parameters and a 68% confidence level $\Delta\chi^2 = 2.3$. See Ref. [11] (p. 815) for a table of $\Delta\chi^2$ for different confidence levels and number of adjustable parameters. In the more general case in which $\chi_0^2/\nu > 1$ and several parameters are adjusted simultaneously eq. 7 is extended to

$$\chi^2 = \chi_0^2 + \Delta\chi^{2'}, \quad \text{where} \quad \Delta\chi^{2'} = \Delta\chi^2 \chi_0^2/\nu. \quad (8)$$

In the study of scattering angular distributions, the experimental data (x_i, y_i) consist in angles and differential cross-sections $(\theta_i, d\sigma_i/d\Omega)$. The theoretical model $f(x_i|\alpha)$ can be either the calculated $d\sigma(\theta_i)/d\Omega$ using the phenomenological Woods-Saxon optical model or the microscopic models involving folding of nuclear densities with appropriated nucleon-nucleon potentials. In this work the São Paulo global microscopic potential (SPP [16, 17]) is used with $\alpha_1 = N_R$ and $\alpha_2 = N_I$ (depth of real and imaginary parts of the potential, respectively).

2.2. Criteria used in previous works

Table 1 presents a non-exhaustive list of experiments studying the TA, either with weakly or tightly bound projectiles. It can be seen that most studies use the standard rule $\chi^2 \leq \chi_0^2 + 1$ (eq. 3) to determine the uncertainties regardless of their χ^2/ν value. We will show in the

next section that due to parameter correlations, this rule gives too small uncertainties bars, even in the best case when $\chi_0^2/\nu \approx 1$, being even worse when $\chi^2/\nu \gg 1$. It is apparent that this problem has been recognized but not clearly acknowledged and, thus, many of the different criteria listed in Table 1 attempted to increase the $\chi^2 \leq \chi_0^2 + 1$ limits. A good example of this can be seen in Ref. [18]. Since their angular distribution data for the $^{12}\text{C} + ^{208}\text{Pb}$ system have an average value $\langle \chi_0^2/\nu \rangle = 6$, the usual criterium $\chi^2 \leq \chi_0^2 + 1$ would have clearly been an underestimation of the parameter uncertainties and an extreme criterium $\chi^2 \leq 2\chi_0^2$ was used, which, as we will show in section 3.1, is an overestimation. In Fig. 1 we show the χ^2 vs. N_R curve corresponding to our reanalysis using SPP of the 84.9 MeV angular distribution of Ref. [18]. The optimum fit is obtained applying a combination of grid, and steepest descent searching routines and gives: $N_{R0} = 0.5738$, $N_{I0} = 0.5173$, $\chi_0^2 = 198$, $\chi_0^2/\nu = 9.9$. The covariance matrix, including the variance of each of the two parameters N_R and N_I and their covariance, is calculated using second derivatives calculated numerically around the minimum [15]. The parabolic approximation of the curve describing χ^2 as a function of N_R is shown in Fig. 1 with dashed lines. Its expression is given by

$$\chi^2 = \frac{1}{\sigma_1^2}(N_R - N_{R0})^2 + \chi_0^2, \quad (9)$$

where σ_1^2 is the variance of N_R . This variance determines the value of $|N_R - N_{R0}|$ that produces a change in one unit in the χ^2 , as in eq. 10a. The solid lines in Fig. 1 represent the values corresponding to a grid on N_R while N_I is optimized. It is seen that the parabolic approximation is quite good even at several σ_1 away from the minimum. Uncertainty limits corresponding to different criteria found in the literature are:

$$\sigma_1 \rightarrow \chi^2 \leq \chi_0^2 + 1 \quad (10a)$$

$$\sigma_2 \rightarrow \chi^2 \leq \chi_0^2 + 2.3 \quad (10b)$$

$$\sigma_3 \rightarrow \chi^2 \leq \chi_0^2 + \chi_0^2/\nu \quad (10c)$$

$$\sigma_4 \rightarrow \chi^2 \leq \chi_0^2 + 2.3\chi_0^2/\nu. \quad (10d)$$

These equations are not meant to represent different confidence limits (CL) but different criteria. In the particular example of Fig. 1, σ_3 represents the 68% CL for the adjustment of the single parameter N_R , considered as uncorrelated with N_I , while σ_4 represents the 68% CL for the simultaneous adjustment of the correlated N_R and N_I . In this case, since $\chi_0^2/\nu = 9.9$, σ_1 and σ_2 do not represent 68% CL. In the parabolic approximation of eq. 9 it holds

$$\sigma_2 = \sqrt{2.3} \sigma_1, \quad \sigma_3 = \sqrt{\chi_0^2/\nu} \sigma_1, \quad \text{and} \quad \sigma_4 = \sqrt{2.3\chi_0^2/\nu} \sigma_1. \quad (11)$$

Perhaps, the great variety of criteria in Table 1 are due to the fact that in most cases the standard rule $\chi^2 \leq \chi_0^2 + 1$ produces too small uncertainties. This turns to be evident when the optimum values of the parameters are in effect changed by their uncertainties: the corresponding change in the angular distributions is often indistinguishable from the optimum ones.

2.3. Error ellipses

One interesting example within low-energy nuclear physics of the use of error ellipses to estimate uncertainties for correlated parameters is presented in Ref. [39]. However, this has not been applied to take into account the correlation between the optical-model parameters. In fact, none of the works listed in Table 1 uses this technique. In our case the ellipses corresponding to the different limits previously mentioned are calculated as

$$\Delta\chi^{2'} = (\boldsymbol{\alpha} - \boldsymbol{\alpha}_0)^T C^{-1} (\boldsymbol{\alpha} - \boldsymbol{\alpha}_0), \quad (12)$$

Table 1. Different criteria used in the calculation of parameter uncertainties in the study of the threshold anomaly.

Figure 1. χ^2 as a function of N_R for $^{12}\text{C} + ^{208}\text{Pb}$ at 84.9 MeV (Plots a) and b) show different scales of the axes). Different criteria for the uncertainty interval of N_R are shown: $\sigma_1 \approx 0.0086$, $\sigma_2 \approx 0.013$, $\sigma_3 \approx 0.0271$, $\sigma_4 \approx 0.041$. The criterium applied in Ref. [18] gives $\sigma_{\text{Santra 2001}} \approx 0.121$.

where $\Delta\chi^{2'}$ is defined in eq.8, the covariance matrix C is calculated for each system and energy and $\alpha - \alpha_0$ represent deviations respect the optimum value of the parameters.

Figure 2 shows three of such ellipses for the $^{12}\text{C} + ^{208}\text{Pb}$ angular distribution at 84.9 MeV corresponding to the σ_1 , σ_3 and σ_4 limits for the determination of the standard uncertainty in both parameters. The limit σ_2 should be used in cases where $(\chi^2/\nu) \approx 1$. In the cases were $(\chi^2/\nu) > 1$, σ_4 should be used. We will show the error ellipses for all energies of both cases studied in Figs. 3 and 5.

2.4. Bootstrap

Bootstrap is one of the many resampling methods designed to go beyond regular statistic test. It creates a number N_B of synthetic data sets, each of them consisting on N data points selected randomly (with reposition) from the original data set of N points (it is desirable to have $N_B \gg N$). On the average a fraction $1/e$ (about 37%) of the N points will be repeated ones (thus having more weight in the fitting procedure) and, consequently, 37% of the elements will not be included. Each synthetic data set is used to fit the parameters of interest. The standard deviation of the N_B values obtained for each parameter is a reliable estimation of its uncertainty. Hence, this procedure gauges the sensitivity of the fitted parameter to each individual data point by the simulation of N_B experiments in which the experimenter could have chosen to repeat the measurement of some of the data points at the cost of missing some others. The bootstrap method has been one of the techniques applied to the evaluation of the half-life of ^{198}Au in Ref. [40]. To the best of our knowledge, bootstrap techniques have not been applied yet to the calculation of nuclear potential parameters and their uncertainties.

In Fig. 2 we show the resulting N_R, N_I points from the adjustment of $N_B = 2200$ synthetic angular distributions. The average and variance converged for $N_B \geq 200$. It is interesting to point out that 76% of the bootstrap points are enclosed by the σ_4 ellipse.

Figure 2. Plot a) shows the bootstrapped values (red points) and the ellipses described in section 2.3 (σ_2 ellipses not shown for clarity). Histograms in b) and c) are the projection of bootstrapped points on the N_R and N_I axis respectively, while the full line shows the much narrower gaussian distribution with standard deviation σ_1 ($\chi \leq \chi_0^2 + 1$) for comparison.

3. Case studies

In the first step to study the $^{12}\text{C} + ^{208}\text{Pb}$ and the $^6\text{Li} + ^{80}\text{Se}$ systems, the optimum N_R , N_I values are calculated as well as the corresponding residuals, covariance matrices and error ellipses. Since a condition of the analysis is the normality of the residuals, the Kolmogorov-Smirnov test has been applied. This statistical test evaluates the maximum difference between the empirical and reference (theoretical) cumulative distribution functions and yields the acceptance or rejection of a null hypothesis at a given confidence level [41].

In our case, we compare to two different null hypothesis: *i*) the residuals follows a normal distribution with mean value $\langle R \rangle = 0$ and variance $\sigma_R^2 = 1$, i.e. $H_{01} : R_i \sim \mathcal{N}(0, 1)$ and *ii*) the residuals follows a normal distribution but in this case with variance $\sigma_R^2 = \chi_0^2/\nu$ i.e. $H_{02} : R_i \sim \mathcal{N}(0, \chi_0^2/\nu)$.

3.1. The $^{12}\text{C} + ^{208}\text{Pb}$ system

As expected, the residuals of the angular distributions of each individual energy, as well as the residuals corresponding to all data taken together, follow $\mathcal{N}(0, \chi_0^2/\nu)$ but do not follow $\mathcal{N}(0, 1)$. Fig. 3 shows the error ellipses corresponding to the limits σ_1 , σ_3 and σ_4 of eq. 10 (σ_2 not shown for clarity) and points (N_R, N_I) representing the results from fitting bootstrapped data sets as explained in section 2.4. For all energies, $N_B \geq 300$. The numbers n_1 , n_2 , n_3 and n_4 indicate the number of these bootstrapped points inside each ellipse (as it has been shown in Fig. 2, expressed as a percentage of N_B). Except for the lowest and highest energies more than 50% of the bootstrapped points are enclosed inside the σ_4 ellipse. In general they extend beyond the last ellipse but keeping the same correlation. If cases c) and h) of this figure a group of points diverge

Figure 3. Distributions of N_R and N_I parameters that best adjust synthetic data sets generated through the bootstrap technique for the $^{12}\text{C} + ^{208}\text{Pb}$ system. The analysis based on the ellipses is described in section 3.3. The uncertainty bars indicate the medium values of the parameter distribution and their standard deviations.

from the main trend. The effect was traced to the influence of one single experimental point in both cases, been the divergent group part of a population in which that point is omitted. In Fig. 4, the parameters and their uncertainties given by the bootstrap method is compared with the ones given by Ref.[18]. It is seen that even though our assigned uncertainties are smaller the character of a regular TA is maintained.

3.2. $^6\text{Li} + ^{80}\text{Se}$ system

Since in this experiment $\chi^2_0/\nu \approx 1$ both null hypothesis almost coincide. The Kolmogorov-Smirnov test indicates that residuals corresponding to all data taken together are normally distributed, and so are individual angular distributions for each energy, except for the data corresponding to 23 and 14.5 MeV. This reveals that for these two energies there is a subtle difference between experimental data and the theoretical model. Even though this difference is statistically significant, it would have remained unnoticed without this analysis. Normalization factors of around 1.6% applied to these angular distributions are enough to make them pass the test, but this may require further analysis. Figure 5 shows the error ellipses and bootstrapped points as in Fig. 2. Here, more than 43% of the bootstrapped points are enclosed inside the σ_4 ellipse. The behavior of the parameters and their uncertainties given by the bootstrap limits is compared with the ones given by in Ref. [24] in Fig. 4.

Figure 4. Comparison between the dispersion relations reported in the original works and those obtained in the present analysis with the bootstrap technique a) for the $^{12}\text{C} + ^{208}\text{Pb}$ system and b) for the $^6\text{Li} + ^{80}\text{Se}$ system. The bootstrap results are slightly displaced in energy for clarity.

Figure 5. Distributions of N_R and N_I parameters that best adjust synthetic data sets generated by the bootstrap technique for the $^6\text{Li} + ^{80}\text{Se}$ system. The analysis based on the ellipses is described in section 3.3. The uncertainty bars indicate the medium values of the parameter distribution and their standard deviations.

4. Conclusions

We have shown that most studies use the standard rule from curve fitting: $\chi^2 \leq \chi_0^2 + 1$ (eq. 3), to determine the uncertainty in fitting parameters (usually N_R and N_I) from experimental data, regardless of their experimental value of χ_0^2/ν . This is not satisfactory even from the point of view of conventional statistic: For the cases where $\chi_0^2/\nu > 1$ that prescription is incorrect and should be replaced by $\chi^2 \leq \chi_0^2 + 2.3\chi_0^2/\nu$ of eq. 10d. Parameters uncertainties which has been already derived using the $\chi^2 \leq \chi_0^2 + 1$ recipe, can be easily scaled up (under the parabolic approximation of eq. 11) by a factor of $\sqrt{2.3\chi_0^2/\nu}$.

The bootstrap resampling method applied in this work produced a more realistic distribution of the parameters as shown in Figs. 2 b) and c). The resulting uncertainties are similar or somewhat larger than the ones obtained with the σ_4 ellipse (eq. 10d).

To judge the kind of TA it is very helpful to look at the series of 2-dim N_R vs. N_I plots with their respective uncertainty ellipses. In this way, the correlation between the parameters can be considered. In Fig. 4 our results, plotted in the conventional way, show a more reliable estimation of the parameter uncertainties than the quoted in the original works (smaller for $^{12}\text{C} + ^{208}\text{Pb}$, similar or slightly larger for $^6\text{Li} + ^{80}\text{Se}$). In these cases, however, the conclusions about the kind of TA was not modified. Further work is in progress to extend the present analysis to other systems, using bootstrap as well as other resampling techniques.
